Screening

ABSTRACT

Background: Delirium is common in critically ill patients with detrimental effects in terms of increased morbidity, mortality, costs, and human suffering. Delirium detection and management depends on systematic screening for delirium, which can be challenging to implement in clinical practice.

Objectives: The aim of this study was to explore how nurses in the intensive care unit perceived the use of Confusion Assessment Method for the Intensive Care Unit (CAM-ICU), the Confusion Assessment Method for the Intensive Care Unit-7 (CAM-ICU-7), and Intensive Care Delirium Screening Checklist (ICDSC) for delirium screening of patients in the intensive care unit.

Methods: This was a cross-sectional, electronic-based survey of nurses' perceptions of delirium screening with the three different instruments for delirium screening. Nurses were asked to grade their perception of the usability of the three instruments and how well they were perceived to detect delirium and delirium symptom changes on a 1- to 6-point Likert scale. Open questions about perceived advantages and disadvantages of each instrument were analysed using the framework method.

Results: One hundred twenty-seven of 167 invited nurses completed the survey and rated the CAM-ICU-7 as faster and easier than the ICDSC, which was more nuanced and reflected changes in the patient's delirium better. Despite being rated as the fastest, easiest, and most used, the CAM-ICU provided less information and was considered inferior to the CAM-ICU-7 and ICDSC. Using familiar instruments made delirium screening easier, but being able to grade and nuance the delirium assessment was experienced as important for clinical practice.

Please cite this article as: Nielsen AH et al., Intensive care unit nurses' perception of three different methods for delirium screening: A survey (DELIS-3), Australian Critical Care, <https://doi.org/10.1016/j.aucc.2022.12.008>

Conclusions: Both the ICDSC and the CAM-ICU-7 were perceived well suited for detection of delirium and reflected changes in delirium intensity. The CAM-ICU was rated as fast and easy but inferior in its ability to grade and nuance the assessment of delirium. Emphasis on clinical meaningfulness and continued education in delirium screening are necessary for adherence to delirium management guidelines.

1. Introduction

Delirium is commonly occurring in the intensive care unit (ICU), and identification depends on systematically screening for detection. Especially the hypoactive form of delirium may be difficult to detect without employment of proper screening tools.¹ Systematic screening can, however, be difficult to implement in clinical practice as nurses may distrust screening instruments and prefer a subjective assessment of the patient's mental status,^{2,3} yet nurses may be engaged in delirium detection if they find it meaningful.^{2,4} In this study, we explore nurses' perception of different delirium screening instruments to gain a deeper understanding of what nurses find useful in clinical practice.

1.1. Background

Delirium is the clinical manifestation of the pathobiological process of acute encephalopathy^{5,6} and should be regarded as brain dysfunction.^{7,8} Delirium is characterised by acute onset, fluctuating symptoms, reduced attention, and altered cognition and is by definition triggered by an organic cause.⁸ Delirium is associated with increased mortality and⁹ increased healthcare costs^{7,10} and might be associated with poorer cognitive outcome⁷ although this is not consistently found in the intensive care population.¹¹ Under all circumstances, delirium is a frightening experience for patients and relatives.¹²

The 2018 Prevention and Management of Pain, Agitation/Sedation, Delirium, Immobility, and Sleep Disruption in Adult Patients in the ICU (PADIS) guideline recommends systematic and regular screening for delirium with validated tools.¹³ Especially hypoactive delirium is difficult to recognise in patients that may be lethargic and withdrawn¹ and consequently may be overlooked by healthcare professionals. Well-known methods for delirium detection in the ICU includes the Confusion Assessment Method for the ICU (CAM-ICU)¹⁴ and the Intensive Care Delirium Screening Checklist (ICDSC).¹⁵ The CAM-ICU assesses inattention and disorganised thinking using prespecified tests,¹⁴ whereas the ICDSC supplements tests of inattention and disorganised thinking with clinical observations of sleep pattern, motor activity, behaviour, and hallucinations.¹⁵ The CAM-ICU has a dichotomous outcome (delirium positive/delirium negative),¹⁴ whereas the ICDSC results in a score between 0 and 8: 0 denotes no delirium, 1–3 denotes subsyndromal delirium, and 4–8 denotes delirium.^{15,16} The Confusion Assessment Method for the Intensive Care Unit-7 (CAM-ICU-7), developed by Khan et al.¹⁷ and building on the CAM-ICU,¹⁴ assesses the same elements as the CAM-ICU. The CAM-ICU-7 has been validated as a measure of delirium severity on a scale from 0 to 7: 0–2 denotes no delirium, 3–5 mild to moderate delirium, and 6–7 severe delirium.¹⁷ Krewulak et al.¹⁸ showed significant correlation between the CAM-ICU-7 and the ICDSC although the ICDSC has not been validated as a measure of delirium severity.

Delirium screening has been shown to be pivotal for efficient delirium management¹; however, systematic and regular delirium screening of ICU patients was negatively affected by distrust in the reliability of screenings instruments, difficulties in using the

instruments when patients were fatigued or losing concentration, and the belief that a clinical judgement of an experienced ICU nurse was more accurate in detection of delirium.¹¹ As delirium has severe negative consequences for patients⁷ and is difficult to detect,^{1,19} there is a need to further explore and understand nurses' perceptions and uses of different delirium screening instruments for ICU patients.

1.2. Aim

The aim of this study was to explore how nurses in the ICU perceived the use of the CAM-ICU, CAM-ICU-7, and ICDSC for delirium screening of patients admitted to the ICU.

2. Methods

This study was an electronic, cross-sectional survey. The survey combined quantitative and qualitative questions and was issued to nurses who had completed delirium screening of ICU patients with three different instruments (the CAM-ICU, the CAM-ICU-7, and the ICDSC) as part of the overarching DELIS-3 study ([ClinicalTrials.gov](https://clinicaltrials.gov) ID NCT04551508).

2.1. Delirium screening instruments

Fifteen of 17 participating ICUs had implemented the Danish version of the CAM-ICU²⁰ for delirium screening, and two ICUs used the Danish version of ICDSC.²¹ The Danish version of the ICDSC was approved by Y. Skrobik, one of the original authors of the ICDSC,¹⁵ and had an important clarification from the original ICDSC as it took into account sedation as a confounder for assessment of consciousness and psychomotor slowing.^{13,22} The CAM-ICU-7 had only recently been translated into Danish²³ and was not used in any Danish ICUs to our knowledge.

2.2. Participants and setting

For this survey, we included a total of 176 nurses from 17 Danish ICUs (11 ICUs in regional hospitals and 6 ICUs in university hospitals) who had participated in the overarching DELIS-3 study. Participants had been recruited because of their interest in delirium in ICU patients. Nine withdrew due to maternity or sick leave or job change, leaving 168 participants. All participants were ICU nurses with more than 6 months' clinical ICU experience. Prior to completing the survey, each nurse had received training in delirium and the use of three different instruments (CAM-ICU, CAM-ICU-7, and ICDSC) for delirium screening followed by bedside training in delirium screening by an ICU nurse experienced in delirium screening. As part of the DELIS-3 study, each participating nurse was asked to screen 10 different ICU patients at least once, each time using the three different instruments. For each screening, the sequence of the screening instruments was randomised to avoid giving preferential treatment to one method. Nurses were not blinded to previous delirium screening results.

2.3. Data collection

The survey included questions about nurses' perceptions of (i) how time-consuming they experienced delirium screening to be, (ii) how difficult they experienced delirium screening, (iii) the perceived ability of the instruments to detect delirium, (iv) the perceived ability of the instruments to detect changes in delirium, (v) experienced advantages and disadvantages related to each instrument, and (vi) to what degree disadvantages were outweighed by the advantages. Questions 1–4 and 6 were rated on a 1- to 6-point Likert scale (1 = not at all, 6 = very much). Question 5 allowed respondents to elaborate in a short text format.

We collected data on the participants' age, ICU work experience, perceived delirium screening competence, and habitual delirium screening method. The questionnaire was pilot tested and amended before use and is available as online supplement.

After completing the screenings or at the end of the DELIS-3 study (whichever came first), each participant received an electronic questionnaire using REDCap electronic data capture tools. Participants were reminded to respond to the survey up to 3 times and could only respond once.

2.4. Data analysis

Quantitative questions were analysed using a mixed model, with three paired t-tests. In addition, we did subanalyses adjusting for age, ICU work experience, perceived delirium screening competence, and habitual delirium screening instrument. No multiple tests were made since data were not independent. For categories with less than 20 respondents, *p*-values were omitted since these data could not be considered normally distributed. In case of missing data, no imputation was attempted. Statistical analysis was performed in STATA.²⁴

Responses for the qualitative question about advantages and disadvantages to the three different screening instruments were analysed using the framework method,²⁵ beginning with familiarisation with the data and inductive coding performed in NVivo.²⁶ A matrix of the instruments and codes (familiarity with screening, professional competency, monitoring delirium, confidence in screening, barriers for screening, documentation) was developed in which data were entered and condensed. Examination of the matrix allowed for the identification of differences and similarities across instruments and formulation of overarching themes.²⁵ During the back-and-forth process of the analysis, we continually reflected on the relationship between data and possible interpretations looking for internal homogeneity and external heterogeneity between themes,²⁷ thus ensuring rigour and trustworthiness.²⁸

2.5. Ethical considerations

All participants were recruited by a nurse specialist in their own department, and all participants gave written, informed consent when responding to the electronic survey. Participants were given the opportunity to withdraw from the study after completing the survey although no one chose to. To protect participant confidentiality, all data were pseudonymised and participants' sex was not recorded as nurses of male sex were less prevalent. The study was registered with Region Central Jutland, identifier 1-16-02-546-20. Approval by the ethics committee was not required by Danish law, however, the study was conducted in accordance with the Helsinki Declaration.²⁹ Data were stored in REDCap at Aarhus University and thereby protected by EU regulations and reported using the Consensus-based Checklist for Reporting of Survey Studies (CROSS) guideline.³⁰

3. Results

A total of 127 of the invited 168 nurses completed the questionnaire (76%). Participants had a mean of 12.2 years (standard deviation [SD]: 8.1) working experience in the ICU and felt competent in delirium screening as indicated on a 6-point Likert scale (mean: 5.1, SD: 0.8). Most nurses (90.1%) had the CAM-ICU as their usual instrument for delirium screening, 8.7% used the ICDSC, and one nurse indicated using the Glasgow Coma Scale for delirium assessment. On average, participants had completed 7.9 delirium screenings using all three instruments (Table 1).

Overall, delirium screening was perceived to be quick and easy to complete, with the ICDSC as the most time-consuming (mean: 3.31, SD: 1.22), followed by the CAM-ICU-7 and CAM-ICU as the fastest (mean: 2.42, SD: 0.99). The CAM-ICU was the easiest (mean: 1.9, SD: 0.95) followed by the CAM-ICU-7 and the ICDSC as the most difficult (mean: 2.93, SD: 1.32). The ICDSC was perceived as the most accurate tool to detect delirium (mean: 4.56, SD: 1.1), closely followed by the CAM-ICU-7 (mean: 4.27, SD: 1.09). The ICDSC was furthermore perceived as the instrument that most accurately reflected a change in the delirium (mean: 4.55, SD: 1.11), followed by the CAM-ICU-7 (mean: 4.12, SD: 1.14) and the CAM-ICU (mean: 3.42, SD: 1.15) (Table 2).

Comparing the three instruments pairwise; the ICDSC was overall evaluated slightly better than the CAM-ICU-7, which was in turn evaluated better than the CAM-ICU (Table 3). The ICDSC was considered slightly more time-consuming (0.41, SD: 1.22, $p = <0.001$) and more difficult to use (0.54, SD: 1.35, $p = <0.001$) than the CAM-ICU-7. However, the ICDSC was perceived as more accurately reflecting the patients' delirium than CAM-ICU-7 (mean difference: 0.29, SD: 1.26, $p = 0.01$) and more accurately reflecting change in the patient's delirium (mean difference: 0.41, SD: 0.86, $p = 0.008$) than the CAM-ICU-7. Advantages of the ICDSC outweighed disadvantages slightly better than the CAM-ICU-7 (mean difference: 0.34, SD: 1.69, $p = 0.029$), whereas the CAM-ICU was inferior to the ICDSC and the CAM-ICU-7 (Table 3).

Dividing nurses into age groups (24–39 years, 40–50 years, 51–65 years) (Table 4) and groups of ICU experience (1–4 years, 5–11 years, >11 years) (Table S1, online supplement only) showed that among the youngest and least experienced nurses, there were no significant differences in their perceptions of the ICDSC and CAM-ICU-7 (Table 4 and S1), whereas the oldest and most experienced nurses consistently favoured the ICDSC over the CAM-ICU-7 (Table 4 and S1). Prior experience with an instrument (Table S2, online supplement only) made the instrument faster and easier to use, whereas feelings of competence did not influence perception of instruments (Table S3, online supplement only).

Overall, the CAM-ICU-7 was slightly faster and easier to use than the ICDSC, whereas the ICDSC better reflected the patient's symptoms and change in symptoms of delirium. Disadvantages were slightly better outweighed by advantages in the ICDSC regardless of prior experience (Fig. 1).

The qualitative data showed that using familiar instruments made delirium screening easier. Being able to grade and nuance the delirium assessment was important to clinical practice, but nurses were very particular when it came to assessments that did not accurately reflect the patients' delirium status (Table 5).

3.1. Using familiar delirium screening instruments and procedures

Most nurses were familiar with the CAM-ICU, and this paved the way for the CAM-ICU-7, which has almost identical items, although the calculation of a score was new to them. Both the CAM-ICU and CAM-ICU-7 were easy to remember, complete, and repeat as needed.

^a Likert scale 1–6 point: 1 = not at all, 6 = very much.

"It's easy to do. Very simple and not time-consuming at all (perhaps because I'm used to it)." (About the CAM-ICU).

The ICDSC was new to most nurses in the study, and at a first glance, the ICDSC felt confusing with much text describing the different elements. However, those who were accustomed to the ICDSC felt that it was easy to use as most of the needed observations were embedded in their usual clinical observations of the patients. A drawback of the ICDSC was that it required good documentation of the patient's status the previous 24 h to be able to complete all items of the ICDSC. Some nurses expressed that it could be difficult to locate these data. The CAM-ICU and the CAM-ICU-7 were less dependent on data from previous shifts; however, knowledge of the patient's habitual status made delirium screening more accurate. The expressed advantage of being familiar with the screening instrument and procedures related to locating necessary data illustrates that it may take time to know any of the instruments well.

3.2. Being able to monitor and grade delirium

Being able to grade the intensity of delirium and monitor delirium over time was a benefit of both the CAM-ICU-7 and ICDSC, who both produced a score that could increase or decrease over time. Nurses found this beneficial as they could initiate non-pharmacological measures to decrease or alleviate the patient's delirium symptoms. The ICDSC resulted in a score that reflected delirium across a whole shift, whereas the CAM-ICU and the CAM-ICU-7 were regarded a snapshot of the patient's delirium that could be repeated as needed and thereby monitored over time.

"It gives a clearer picture of the deliriousness, whether it gets better or worse and it's useful for planning interventions". (About the CAM-ICU-7).

Yet, some nurses were disinclined to follow the delirium screening protocol because they were concerned about troubling patients who were clearly delirious. Also, in patients who were not delirious, they found it difficult to ask the questions of unorganised thinking in the CAM-ICU and CAM-ICU-7, which they found "silly".

"I find it difficult to ask the patient all those silly questions – especially when the patient is completely awake and alert". (About the CAM-ICU and CAM-ICU-7).

Besides grading delirium, nurses emphasised that they used their professional judgement to qualitatively assess the patients' delirium. Especially the CAM-ICU but also the CAM-ICU-7 needed to be supplemented by further assessments of delirium features such as agitation or sedation, sleep–wake cycle, and hallucinations to get the full picture of the patient's delirium. Such an assessment

was provided by the ICDCS. Nurses, who were new to the ICDCS, expressed that the ICDCS opened their eyes to the subtle yet complex symptoms of delirium, and in that sense, the ICDCS was formative and increased the participating nurses' knowledge about delirium.

"I was surprised that patients who scored negative for delirium still had frightening dreams". (About the ICDCS).

3.3. Having confidence in delirium screening

For delirium screening to be clinically meaningful, nurses needed to feel confident in the results. Across all three instruments, nurses found some patients difficult to assess, e.g., patients who were too feeble to move their hands, had difficulties hearing or seeing, were tired, were sedated, or were suffering from traumatic brain injuries. In these cases, nurses would consider a positive delirium screening as a false positive. When patients were screened as delirium negative on the CAM-ICU or CAM-ICU-7 despite suffering from hallucinations or disturbed sleep-wake cycles, nurses would consider this a false negative screening. Some nurses found patients who were unable to collaborate with delirium screening in the ICU unsuitable for delirium screening, which suggests that there may be some basic misunderstanding on how lack of attention towards screening should be interpreted.

"It's imperative that the patient can collaborate on screening". (About the CAM-ICU).

The CAM-ICU and the CAM-ICU-7 used the same approach for delirium screening every time which was considered a strength, whereas the ICDCS relied on a combination of observations of patient behaviour and questions to the patient. Taking more features into account, nurses found the ICDCS more sensitive for delirium detection and change in the patient's symptoms.

"That there is a dialogue with the patient about their experiences of hallucinations, nightmares and sleep. It includes the patient's own experiences". (About the ICDCS).

The ICDCS had more room for the nurses' subjective assessment of the patient even when based on a dialogue with the patient. This could be considered a disadvantage compared to the more standardised approaches of the CAM-ICU and the CAM-ICU-7. However, some elements of the ICDCS were open to different interpretation among nurses, who found the descriptions ambiguous and difficult to use in practice and led nurses to perceive the ICDCS as dependent on the nurse.

"Some things were strange like 'inappropriate speech or mood'. What is that and how do I know it?" (About the ICDCS).

4. Discussion

This survey study found that nurses rated the CAM-ICU-7 as faster and easier to use than the ICDCS, which instead was more nuanced and better reflected changes in the patient's delirium. The CAM-ICU was rated as the fastest and easiest and most commonly used, but it provided less information and was therefore considered inferior to the two other instruments. In comparison, a meta-analysis³¹ showed good predictive values of both the CAM-ICU (sensitivity: 0.84, specificity: 0.95) and the ICDCS (sensitivity: 0.83, specificity: 0.87), but present study suggests that clinical relevance of delirium screening may also be determined by direct applicability of the results in clinical practice.

Nurses wanted to use their professional judgement when assessing patients' delirium, which fit well with the ICDCS procedure of observing the patient throughout the shift. A study by Kvande et al.³² found that assessing changes in the ICU patient's condition required the skilled ICU nurses to be sensitive to subtle changes in the patient's unique situation. Comparing the ICDCS to the CAM-ICU-7, the ICDCS has more room for a qualitative, nuanced assessment over time, which may explain why nurses found this instrument more sensitive to delirium changes than the CAM-ICU-7. Although most nurses viewed themselves as very competent in delirium screening, the ICDCS broadened their clinical understanding of delirium. This suggests that there is an ongoing need for

Table 4

CAM-ICU, Confusion Assessment Method for the Intensive Care Unit; CAM-ICU-7, Confusion Assessment Method for the Intensive Care Unit-7; ICDCS, Intensive Care Delirium Screening Checklist; SD, standard deviation.

^a Likert scale 1–6 point: 1 = not at all, 6 = very much.

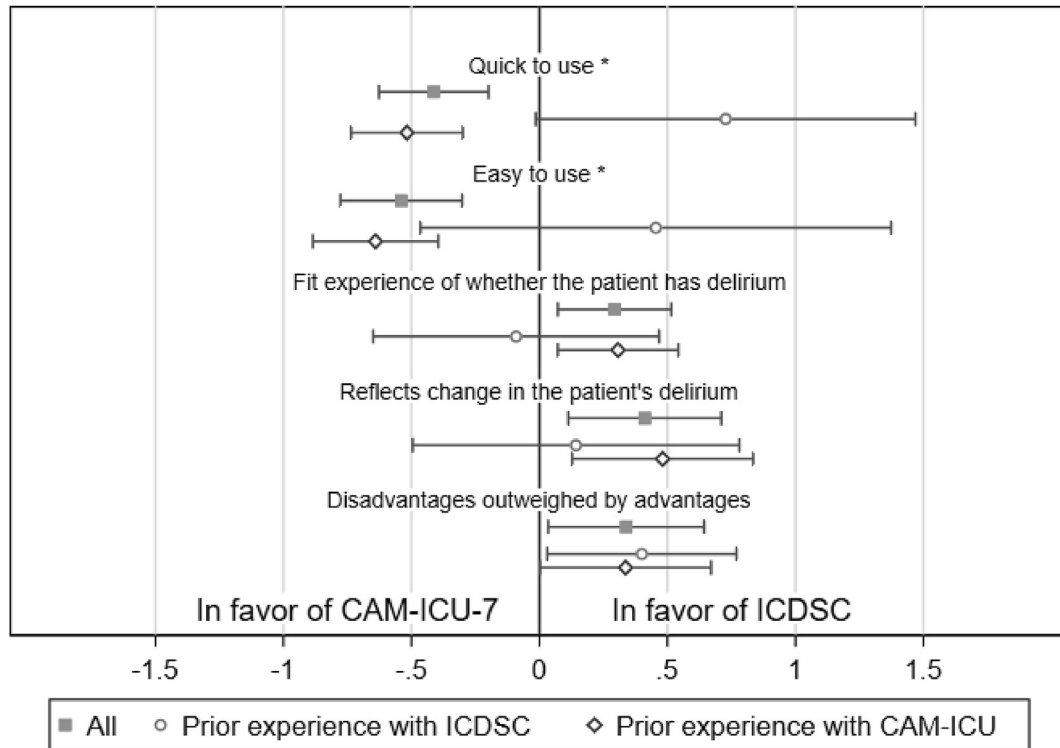

Fig. 1. Comparison of CAM-ICU-7 and ICDSC. * The question has been reversed so that a negative score is in favour of the CAM-ICU-7. CAM-ICU, Confusion Assessment Method for the Intensive Care Unit; CAM-ICU-7, Confusion Assessment Method for the Intensive Care Unit-7; ICDSC, Intensive Care Delirium Screening Checklist.

education on delirium management even in nurses with self-rated high competency in delirium screening. This is supported by a Dutch survey of ICU professionals by Trogrlić et al.,³³ which showed that while all respondents (mainly nurses) agreed that delirium screening was useful, respondents had less confidence in their ability to reliably use a validated instrument.³³ A paper by Hermes et al.³⁴ discussed management of delirium and lack of adherence to evidence-based guidelines and found that educational gaps in delirium management may limit adherence to guideline-based care and thereby negatively affect patient care. Thus, a continued focus on knowledge of delirium and beliefs in the relevance of screening are necessary. Choosing an instrument that resonates with nurses' observation practices may therefore further the successful implementation of delirium screening.

In this study, we found that across all three instruments, nurses found some patients difficult or impossible to assess for delirium.

As all instruments required patients to answer questions, nurses were sometimes at loss when patients did not respond properly due to intubation, sedation, or lethargy. An American study explored inappropriate unable-to-assess responses to the CAM-ICU and found that these were associated with sedation, mechanical ventilation, night shift, higher age, and non-white population.³⁵ However, Pandharipande et al.¹⁹ refuted the unsuitability of certain patient groups for screening and argued that delirium screening is possible albeit difficult in neurologically injured patients, children, and cognitively impaired to mention some groups often relegated to unsystematised assessment only. Moreover, we found that nurses sometimes doubted the results from delirium screening talking about false positives and false negatives. While it was a strength that healthcare professionals were critical to the reliability of procedures, it also illustrated that screening results must be meaningful and applicable to the clinical context. Choosing a

Table 5 Perceived advantages and disadvantages of delirium screening.

	Advantages	Disadvantages
CAM-ICU	<ul style="list-style-type: none"> • Very fast and easy to repeat • Well known • Standardised screening method 	<ul style="list-style-type: none"> • Unnuanced • Does not quantify delirium intensity • Nurses found questions silly
CAM-ICU-7	<ul style="list-style-type: none"> • Fast and easy to repeat • Very alike CAM-ICU • Graded delirium intensity • Standardised screening method 	<ul style="list-style-type: none"> • Lacked a nuanced assessment of delirium symptoms • Nurses found questions silly • All elements had to be assessed
ICDSC	<ul style="list-style-type: none"> • Nuanced assessment of delirium symptoms • Graded delirium intensity • Prompted nurses' reflections on delirium symptoms 	<ul style="list-style-type: none"> • Extensive • Not well known • Relied on good documentation • Unclear screening procedure

delirium screening instrument that allows for grading of delirium intensity may be one way to achieve more meaningful delirium screenings and thereby increase the adherence to delirium management protocols.

4.1. Strengths and limitations

A limitation of the study was that not all nurses had screened 10 different patients for delirium, and only a minor part had screened the same delirious patient several times using all three instruments, thereby limiting their ability to assess detection of change in delirium features. Moreover, most nurses were used to the CAM-ICU and may therefore naturally have found the CAM-ICU-7 easier and faster given that the items are nearly identical. The small number of nurses using the ICDSC may have biased our findings in favour of the CAM-ICU or the CAM-ICU-7. However, there may also be a certain novelty effect to the ICDSC that taught nurses about delirium, which would probably wear off in time. When using the screening instruments in their clinical practice, nurses were not blinded to the patients' previous screening results, and hence, expectation bias cannot be ruled out. However, this risk was minimised by randomising the order of screening instruments and the fluctuating quality of delirium well known to ICU clinicians. The three instruments used in this study were internationally well known and translated using WHO's guidelines for translating instruments.^{21,23,36}

5. Conclusion

Both the ICDSC and the CAM-ICU-7 were perceived to detect delirium and reflect changes in delirium intensity well, while the CAM-ICU was fast and easy but lacks ability to grade and nuance the assessment of delirium. Disadvantages were outweighed by advantages slightly better in the ICDSC than the CAM-ICU-7, but prior knowledge of an instrument or local preferences may determine which instrument to implement when predictive values of instruments are comparable. Emphasis on clinical meaningfulness and continued education in delirium screening are necessary for increasing adherence to delirium management guidelines.
